ABSTRACT

Results from molecular phylogenetic investigations of Old and New World Artemisia species, and Beringian species in particular, have led to the reevaluation of certain taxa with broad disjunctions. One such taxon, Artemisia rupestris spp. woodii Neilson, is endemic to the southwestern Yukon Territory, Canada and represents the only North American occurrence of the Eurasian species A. rupestris. Based on a reexamination of specimens, molecular evidence, and geographic considerations, subspecies woodii is judged to be distinct from its Eurasian congener and is elevated to specific rank as: Artemisia woodii (Neilson) C. Riggins, stat. nov. Phytologia 94(3): 301-304 (December 1, 2012).

KEY WORDS: Artemisia, Asteraceae, Anthemideae, Yukon Territory, Canada

The Eurasian species A. rupestris L. is represented in North America by a single taxon, A. rupestris ssp. woodii Neilson, which is only found in two highly localized areas of southwestern Yukon Territory, Canada (Hoefs et al., 1983). As part of ongoing investigations of New and Old World Artemisia species, the status of this taxon was reevaluated in light of molecular nrITS and plastid DNA evidence (Riggins and Seigler, in press) and a detailed assessment of morphological characters. During the course of these studies it became apparent that this subspecies is distinct from the Eurasian A. rupestris and associated North American taxa within Artemisia (sensu Shultz, 2006) and so is here elevated to specific status as follows:
Artemisia woodii (Neilson) C. Riggins, **stat. nov.**

Neilson (1968) originally described *A. rupestris* ssp. *woodii* from a collection made in the Kluane Lake area of the Yukon Territory, stating that “This plant has no morphologically similar relative in North America.” He distinguished ssp. *woodii* from the typical Eurasian *A. rupestris* primarily by having broader, rounder phyllaries with scarios, iridescent margins and a reduced number of bracts subtending the capitula. Neilson also noted that the leaf lobes of ssp. *woodii* tended to be more blunt or obtuse in comparison to the acute tips common in the Eurasian material. While acknowledging a superficial resemblance to *A. frigida* Willd. in habit, he further commented that ssp. *woodii* differed from the former by consistently having coarse hairs on the receptacle (sometimes absent in populations of *A. frigida*) and dark green, sticky-glandular leaves.

Almost simultaneous with Neilson’s publication, Welsh (1968) described *A. frigida* var. *williamsae* Welsh from a collection on the lakeshore at Kluane Lake that featured near glabrous receptacles and larger capitula than typical *A. frigida*. Welsh (1974) later considered *A. rupestris* ssp. *woodii* as a synonym for *A. frigida* var. *williamsae*, but Cody (2000) correctly pointed out that the two taxa are not one and the same and that “a form [of *A. frigida*] with glabrous receptacles found in the Kluane Lake area (var. *williamsae* Welsh) should not be confused with the densely glandular-dotted *A. rupestris* ssp. *woodii*, which is endemic to alpine areas in southwestern Yukon Territory.” Comparisons of the holotype (BRY; Williams 1369) and an isotype (OSU) of var. *williamsae* support Cody’s observations. In addition to the presence of viscous glands, *A. woodii* is further distinguished from *A. frigida* by its bright to dark green appearance, its narrow racemiform or spiciform synflorescences (usually paniculiform in *A. frigida*), and slightly larger involucres (5-6 x 6-8 mm) subtended by short linear green bracts. Although both taxa do share a general area
of sympatry in the Yukon Territory, there are no apparent signs of intergradation in the material I have examined.

*Artemisia woodii* is a low mat-forming perennial found on dry well-drained slopes with a southern exposure ca. 800-1900 m in the mountains around Kluane Lake and in one other locality in southwestern Yukon Territory (Hoefs et al., 1983; Cody, 2000). These populations are approximately 5200 km from the nearest easternmost Eurasian populations of *A. rupestris* from the Vilyuy River tributary of the Lena River (see range maps in Hultén, 1968 and Jäger, 1987). *Artemisia rupestris* has its main range centered in the steppe and alpine zones of central Siberia (Altai) with extensions from Kazakhstan to Mongolia and northern Afghanistan, but disjunct populations are also found in the Baltic Region of Northern Europe (where the type was first described), central Germany, and in the Ural Mountains. While the ploidy of *A. woodii* is unknown at present, the diploid (2n=18) condition seems to predominate in Eurasian populations of *A. rupestris*, although there is one count from the Russian Altai that appears to be hypotetraploid (2n=34) (Ehrendorfer, 1964; Goldblatt and Johnson, 2010). It is in the Altai and Lake Baikal areas that plants of *A. rupestris* tend to display the greatest variation in morphology and ecological preference, but there are consistent differences in habit, leaf morphology, and floral bract number in comparison to specimens of *A. woodii*.

In summary, the aforementioned distinctions coupled with molecular evidence that places the Eurasian *A. rupestris* and the North American *A. woodii* in separate clades (Riggins and Seigler, in press) warrant their recognition as distinct species.

**ACKNOWLEDGMENTS**

I thank Dr. Bruce Bennett, of the Yukon Conservation Data Centre in Whitehorse, Yukon, for reviewing the manuscript and generously sharing his field notes and images of this species. Dr. Lee Crane, Illinois Natural History Survey, is also acknowledged for kindly reviewing the manuscript. Thanks also to the curators of ALA, ALTA, CAN, ILLS, and UBC for the loan of specimens for study.
